Analysis Report: Establishing a Concordance between PASEC and TIMSS/PIRLS

## UNESCO

The constitution of the United Nations Educational, Scientific and Cultural Organization (UNESCO) was adopted by 20 countries at the London Conference in November 1945 and entered into effect on 4 November 1946. The Organization currently has 195 Member States and 11 Associate Members.

The main objective of UNESCO is to contribute to peace and security in the world by promoting collaboration among nations through education, science, culture and communication in order to foster universal respect for justice, the rule of law, and the human rights and fundamental freedoms that are affirmed for the peoples of the world, without distinction of race, sex, language or religion, by the Charter of the United Nations.

To fulfill its mandate, UNESCO performs five principal functions: 1) prospective studies on education, science, culture and communication for tomorrow's world; 2) the advancement, transfer and sharing of knowledge through research, training and teaching activities; 3) standard-setting actions for the preparation and adoption of internal instruments and statutory recommendations; 4) expertise through technical cooperation to Member States for their development policies and projects; and 5) the exchange of specialized information.

## UNESCO Institute for Statistics

The UNESCO Institute for Statistics (UIS) is the statistical office of UNESCO and is the UN depository for global statistics in the fields of education, science, technology and innovation, culture and communication. The UIS was established in 1999. It was created to improve UNESCO's statistical programme and to develop and deliver the timely, accurate and policy-relevant statistics needed in today's increasingly complex and rapidly changing social, political and economic environments.

## 1. Summary

This report is concerned with establishing a concordance between the regional PASEC and the international TIMSS and PIRLS achievement scales in francophone Sub-Saharan countries.

The Rosetta Stone study consists of two assessment parts. The first part is the PASEC assessment including the PASEC context questionnaire. The second part is the Rosetta Stone assessment comprising test booklets with easier item blocks and passages from TIMSS and PIRLS. Both assessment parts were administered in three PASEC countries to the same students on two consecutive days.

Analyses were conducted using classical item statistics, item response theory (IRT) and population modeling. They comprise the evaluation of the data quality, evaluation of the psychometric quality of the instruments, establishing common scales across countries and assessments, and constructing concordance tables which account for the uncertainty of the measurement (measurement error).

The key findings can be summarized as follows:

- The difficulty of the selected TIMSS and PIRLS item blocks and passages are appropriate for the Rosetta Stone analysis and the goals of the study.
- Comparable PASEC and Rosetta Stone IRT scales could be established across countries.
- Comparable IRT scales could be established across Rosetta Stone and TIMSS/PIRLS.
- Latent correlations in multidimensional IRT models between PASEC mathematics and TIMSS ( $r=.81-.86$ ) and PASEC reading and PIRLS ( $r=.78-.83$ ) suggest that constructs are not identical but similar enough to enable a concordance.
- Population models were able to be estimated providing proficiency distributions for PASEC and Rosetta Stone scales.
- Plausible values (PVs) for PASEC scales were imputed independently by the TIMSS \& PIRLS International Study Center based on the Rosetta Stone study data for validation purposes. They were found to be highly correlated to the PVs provided by the PASEC team (PASEC mathematics: $r=.96-.97$; PASEC reading: $r=.96-.98$ ) indicating very good agreement of analytic processes.
- Moreover, country means based on PVs for PASEC scales provided by the PASEC team were compared to country means based on the published PASEC 2019 PVs and were found to be very similar. This is indicating that the Rosetta Stone student sample is comparable to the PASEC 2019 student sample.
- Population models were applied to the Rosetta Stone data to obtain posterior means and PVs for TIMSS numeracy and PIRLS literacy.
- Estimates from both assessments, PASEC and Rosetta Stone, were used to establish concordance tables that provide a conditional distribution on the TIMSS and PIRLS scales for a range of PASEC score levels.
- The concordance should be used with care, being aware of the limitations of country participation and sample sizes, and differences between assessments.
- The concordance provides a projection and not a direct linking of scales. However, when used and interpreted properly, concordance tables can provide useful and valuable information by comparing regional assessment results with international benchmarks.
- New countries seeking a concordance between PASEC and TIMSS and PIRLS are encouraged to participate in a Rosetta Stone study first.

The following sections in this report describe the instruments and design of the Rosetta Stone linking study, the psychometric analyses, and the construction of the concordance tables as well as their limitations and appropriate use and interpretation.

## 2. Introduction

IEA's Rosetta Stone study is designed to measure global progress toward the United Nations (UN) Sustainable Development Goal 4 for quality in education (SDG 4, Target 4.1) by relating different regional assessment programs to TIMSS (Trends in International Mathematics and Science Study) and PIRLS (Progress in International Reading Literacy Study) international long-standing metrics and benchmarks of achievement. The goal is to provide participating countries, who participated in regional assessments but not in TIMSS and PIRLS, with information about the proportions of primary school students that have achieved established international proficiency levels in literacy and numeracy for allowing international comparisons.

This analysis report describes the study, methods, and analysis conducted to establish a concordance between the Programme for the Analysis of Education Systems (PASEC; Programme d'Analyse des Systèmes Éducatifs) in francophone Sub-Saharan countries and TIMSS and PIRLS. PASEC assesses student achievement in mathematics, reading, and listening comprehension at grades two and six (i.e., at the beginning and end of primary) and is conducted by the Conference of Ministers of Education of French-Speaking Countries (CONFEMEN).

To construct the concordance, the 2019 PASEC assessment was administered to students at the sixth grade together with the Rosetta Stone linking booklets that contained items from TIMSS and PIRLS. The content of PASEC's mathematics assessment was expected to align well with the TIMSS fourth grade assessments in numeracy and mathematics. Similarly, the content of PASEC's reading assessments was expected to align with the PIRLS fourth grade assessment in literacy and reading comprehension. The TIMSS \& PIRLS International Study Center at Boston College was responsible for the development of the Rosetta Stone assessment, the psychometric analysis, and the establishment of the concordance tables.

The overarching goal is to construct a concordance table that projects the score distributions estimated from the PASEC mathematics and reading assessments to distributions on TIMSS and PIRLS, respectively. The concordance table would therefore represent the "Rosetta Stone", analogous to the original Rosetta Stone which provided a link between Greek and Egyptian hieroglyphics, that enables a translation between the countries' regional assessment results and the TIMSS and PIRLS achievement scales. Countries participating in the regional assessments can then use the translations to estimate percentages of their students that could be expected to reach the TIMSS and PIRLS international benchmarks.

The Rosetta Stone study for PASEC is a collaborative project between the UNESCO Institute for Statistics (UIS), the PASEC study center (CONFEMEN), IEA, and the TIMSS \& PIRLS International Study Center at Boston College, as well as the national teams of the participating countries Burundi, Guinea, and Senegal. Questions about linking design, the data analyses, and the report for the Rosetta Stone study for PASEC should be directed to the TIMSS \& PIRLS International Study Center at Boston College (timssandpirls@bc.edu).

## 3. Rosetta Stone Instruments and Test Design

One of the major goals and design principles of large-scale surveys of student achievement is to provide valid comparisons across student populations based on broad coverage of the achievement domain. This usually translates into a large number of achievement items, only a fraction of which can be administered to any one student given the available testing time. Therefore, Rosetta Stone is based on a matrix-sampling booklet design where each student was administered only a subset of the selected item pools. Moreover, a subset of less difficult TIMSS and PIRLS item blocks and passages was used to best target the difficulty
of the assessment for participating countries. The Rosetta Stone study comprises two assessment parts. The first part is the PASEC assessment including the PASEC achievement items and PASEC context questionnaire. The second part is the centerpiece of the study, the Rosetta Stone assessment part consisting of test booklets with easier TIMSS item blocks and passages and easier PIRLS passages. More precisely, items come from TIMSS Numeracy 2015, TIMSS 2019 less difficult (LD) and PIRLS Literacy 2016. In total, eight less difficult mathematics item blocks and four literacy passages were selected. Exhibit 3.1 provides the number of items and source for each item block and passage. Both assessment parts were administered as paper-based assessments to the same students. Each student was administered one PASEC booklet on the first day and one Rosetta Stone booklet on the second day. A description of the PASEC 2019 booklet design can be found in the related PASEC 2019 report (PASEC, 2020).

Exhibit 3.1: Rosetta Stone Linking Item Blocks and Passages

|  | Source | Number of Items |
| :---: | :--- | :---: |
| TIMSS Blocks |  | 13 |
| N01 | TIMSS Numeracy 2015 - N01 | 14 |
| N02 | TIMSS 2019 LD - MN04 | 13 |
| N03 | TIMSS 2019 LD - MN07 | 13 |
| N04 | TIMSS 2019 LD - MN05 | 13 |
| N05 | TIMSS 2019 LD - MN01 | 14 |
| N07 | TIMSS 2019 LD - MN14 | 13 |
| N08 | TIMSS 2019 LD - MN03 | 12 |
| PIRLS Passages | TIMSS 2019 LD - MN09 | 105 |
| L01 |  | Total TIMSS Items |
| L02 | PIRLS Literacy 2016 - Baghita's Perfect Orange (Literary) | 16 |
| L03 | PIRLS Literacy 2016 - African Rhinos (Informational) | 17 |
| L04 | PIRLS Literacy 2016 - The Pearl (Literary) | 15 |
|  | PIRLS Literacy 2016 - Ants (Informational) | 14 |
|  |  | $\mathbf{T o t a l}$ PIRLS Items |

Exhibit 3.2 illustrates the design for the Rosetta Stone assessment part, which was arranged into eight linking booklets. Each block or passage appeared twice in a balanced incomplete block design. The numeracy blocks appeared in different positions (at the beginning or the end of a booklet) to counterbalance possible position effects. Students had 40 minutes to complete each part of the linking booklet, with a short break in between.

## 4. Analysis Overview and Sample

To establish concordance tables, the analysis of the data proceeded in four steps. These steps are briefly described here and then in more detail in sections 5 to 11 . First, data quality was evaluated based on classical item statistics and an analysis of nonresponse (section 5). Second, IRT models were used to further examine the psychometric quality of the assessment booklets and for constructing comparable PASEC and Rosetta Stone scales across student populations (sections 6 and 7). Third, population models were used to impute plausible values (PVs) separately for PASEC and Rosetta Stone (sections 8 and 9). Fourth, concordance tables were established based on posterior means and PVs from the population models (sections 10 and 11). The analysis was performed on data from three PASEC countries using sample weights provided to the TIMSS \& PIRLS International Study Center.

Exhibit 4.1 provides the sample sizes for each country available for the scaling and population modeling. Cases with sample weights and responses to achievement items (PASEC items, Rosetta Stone items, or both) were included in the analysis while cases with responses only to the PASEC context questionnaire items were excluded. The sample size and number of schools per country in the Rosetta Stone study are smaller in comparison to the full TIMSS and PIRLS assessments where the approximate minimum sample includes 150 schools and 4,500 students for most countries.

Exhibit 4.1: Rosetta Stone Sample Sizes per Country

|  | Country | Number of <br> Students | Number of <br> Schools |
| :--- | :---: | :---: | :---: |
| Burundi | 2,304 | 100 | Number of <br> Classes |
| Guinea | 2,252 | 100 | 100 |
| Senegal | 2,072 | 99 | 100 |
| Total | $\mathbf{6 , 6 2 8}$ | $\mathbf{2 9 9}$ | 99 |

The main goal of the IRT scaling was to establish comparable scales across countries and across the Rosetta Stone and the TIMSS/PIRLS assessments as the basis for a concordance. While PASEC items were already calibrated by the PASEC team, which also provided the PVs for PASEC, the TIMSS \& PIRLS International Study Center performed IRT scaling and population modeling for the Rosetta Stone linking items. For validation and replication purposes, the PASEC items were re-calibrated as well. The following IRT models were estimated:

1. Comparability of PASEC items across countries: For evaluating the psychometric properties and cross-country comparability of the PASEC items, common item parameters were estimated across countries and item fit statistics were examined for all item-by-country combinations. Resulting item parameters were used to replicate and validate the PASEC PVs that were received from the PASEC team.
2. Comparability of linking items across countries and assessments: To achieve comparable scales across Rosetta Stone and TIMSS/PIRLS, item parameters for linking items were borrowed from TIMSS and PIRLS and fixed in the analysis for all countries. Item fit was examined for all item-by-country combinations.
3. Comparability of PASEC and Rosetta Stone constructs: Through multidimensional IRT models, latent correlations between PASEC and Rosetta Stone scales were estimated to evaluate whether the PASEC mathematics and reading scales are sufficiently similar to the TIMSS and PIRLS scales for establishing a meaningful concordance between them.

The estimated item parameters from the IRT scaling were used in the population models together with context variables from the PASEC background questionnaire for imputing PVs. The population modeling was performed at the country-level and separately for PASEC and Rosetta Stone linking data. After the comparability and accuracy of the population modeling approaches used in PASEC and in the Rosetta Stone study was confirmed (by re-estimating the PASEC PVs), the posterior means and PVs from the population models were used for constructing concordance tables, one for reading and one for mathematics. Sections 6 to 9 provide a more detailed description of all IRT and population models, and their application to the Rosetta Stone and PASEC data.

## 5. Data Quality Evaluation

Data quality was evaluated using classical item statistics (percent correct and item-total correlations) and examining item-level nonresponse variability. Exhibits 5.1 and 5.2 provide the average percent of correct responses and the average item-total correlation for each Rosetta Stone and PASEC item block and passage by country. The percent of correct responses show that the TIMSS and PIRLS item blocks and passages are more difficult for the PASEC population than the PASEC mathematics and reading item blocks. The
item-total correlations indicate that TIMSS and PIRLS item blocks and passages exhibit similar medium discriminations as PASEC item blocks.

Exhibits 5.3 and 5.4 illustrate the average item difficulty ( $\mathrm{P}+$ ) by item block and passage averaged across countries for PIRLS literacy and PASEC reading and for TIMSS numeracy and PASEC mathematics, respectively. In both figures the blue dots indicate the average $\mathrm{P}+$ for the specific item blocks and passages while the red line marks the $50 \%$ level as means of comparison. Both figures, as well as the table in Exhibit 5.1, show that TIMSS and PIRLS item blocks and passages tend to be somewhat more difficult than PASEC item blocks and passages within and across countries, but that the difficulty is at an appropriate level for the Rosetta Stone analyses.

Exhibit 5.3: Average Item Difficulty (percent correct) by Item Block/Passage for PIRLS Literacy and PASEC Reading

Exhibit 5.4: Average Item difficulty (percent correct) by Item Block for TIMSS Numeracy and PASEC Mathematics

Exhibits 5.5 and 5.6 illustrate the average percent of omitted (OM) and not reached (NR) items for each PASEC and Rosetta Stone item block and passage. The NR rates are small enough and consistent enough across countries and item blocks/passages to not be of any concern. OM rates are higher for Rosetta Stone item blocks across all countries, with the exception of literacy passages in Senegal. Senegal has the lowest OM rates across Rosetta Stone item blocks/passages, while Burundi has the lowest OM rates across PASEC item blocks. Guinea has the highest OM rates across all item blocks/passages.

## 6. IRT Models

Section 6 describes item response theory (IRT) models and the estimation of item parameters and student proficiencies, in general. This is followed by section 7 which describes the application of IRT scaling in Rosetta Stone specifically and the PASEC item re-calibration.

### 6.1 IRT Scaling in Large-Scale Assessments

Given the complexities of the data collection and the need to describe student achievement on a scale that represents the entirety of the assessment frameworks, large-scale assessments such as TIMSS, PIRLS, or Rosetta Stone rely on IRT scaling to provide accurate measures of student proficiency distributions. Item Response Theory (IRT; Lord \& Novick, 1968) has become one of the most important tools of educational measurement as it provides a flexible framework for estimating proficiency scores from students' responses to test items. IRT is particularly well suited to handle data collection designs in which
not all students are tested with all items. The assumptions made for enabling IRT methods to handle these types of designs, commonly known as balanced incomplete block designs (e.g., von Davier, Sinharay, Oranje \& Beaton, 2006; von Davier \& Sinharay, 2013), can be described and tested formally (e.g., Fischer, 1981; Zermelo, 1929).

In terms of the mathematical notation used in this report, the item response variables on an assessment are denoted by for items $i=1, \ldots, I$. The set of responses to these items is $\boldsymbol{x}_{v}=\left(x_{v 1}, \ldots, x_{v i}\right)$ for student $v$. For simplicity, we assume $x_{v i}=1$ denotes a correct response and $x_{v i}=0$ denotes an incorrect response. The expected achievement is assumed to be a function of an underlying latent proficiency variable, often in IRT denoted by $\boldsymbol{\theta}_{\boldsymbol{v}}$, a real-valued variable. Then, we can write:

$$
\begin{equation*}
P\left(\boldsymbol{x}_{\boldsymbol{v}} \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right)=\prod_{i=1}^{I} P\left(x_{v i} \mid \theta_{v} ; \zeta_{i}\right) \tag{6.1}
\end{equation*}
$$

where $P\left(x_{v i} \mid \theta_{v} ; \zeta_{i}\right)$ represents the probability of an either correct or incorrect response of a respondent with ability $\boldsymbol{\theta}_{\boldsymbol{v}}$ and an item with a certain characteristic $\zeta_{i}$. In IRT, these item-specific effects are referred to as item parameters. Equation (6.1) is a statistical model describing the probability of a set of the observed response given ability $\boldsymbol{\theta}_{\boldsymbol{v}}$. This collective probability is the product of the individual item probabilities.

Many IRT models used in educational measurement can be understood as relatively straightforward generalizations of the approach shown in equation (6.1). While PASEC uses the Rasch model, TIMSS and PIRLS use the 3PL model for multiple-choice items, the 2PL model for constructed-response items worth 1 score point, and the GPCM for constructed-response items worth more than 1 score point. The following section describes these models in more detail.

### 6.2 IRT Models for Dichotomous Items: Rasch Model, 2PL Model and 3PL Model

The Rasch model and the two- and three-parameter logistic (2PL and 3PL) models are suitable for items with only two response categories (i.e., dichotomously scored items). The 2PL model (Birnbaum, 1968, in Lord \& Novick, 1968) is a generalization of the Rasch model (Rasch, 1960), which assumes that the probability of a correct response to item $i$ depends only on the difference between the ability level $\boldsymbol{\theta}_{\boldsymbol{v}}$ of respondent $v$ and the difficulty of the item $b_{i}$. But in addition, the 2PL allows that for every item, the association between this difference and the response probability can depend on an additional item discrimination (or slope) parameter $a_{i}$, characterizing its sensitivity to proficiency. The 3PL model (Birnbaum, 1968, in Lord \& Novick, 1968) generalizes the 2PL model by additionally assuming a pseudo guessing parameter $c_{i}$. Under the 3PL model the response probability to an item is given as a function of the person parameter and the three item parameters; and it can be written as follows:

$$
\begin{equation*}
P\left(x=1 \mid \boldsymbol{\theta}_{v} ; \boldsymbol{\zeta}_{i}\right)=c_{i}+\left(1-c_{i}\right) \frac{\exp \left(a_{i}\left(\theta_{v}-b_{i}\right)\right)}{1+\exp \left(a_{i}\left(\theta_{v}-b_{i}\right)\right)} \tag{6.2}
\end{equation*}
$$

The 3PL is a popular choice for binary scored multiple-choice items. If $c_{i}$ is set to 0.0 , equation (6.2) yields the 2PL model for 1-point constructed response items.

### 6.3 IRT Model for Polytomous Items: GPCM

A model frequently used for binary and polytomous ordinal items (items worth up to 2 points in TIMSS and items worth up to 3 points in PIRLS) is the generalized partial credit model (GPCM; Muraki, 1992), given by:

$$
\begin{equation*}
P_{i}\left(x \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right)=\frac{\exp \left(a_{i}\left(x \theta_{v}-b_{i x}\right)\right)}{1+\sum_{z=1}^{m_{i}} \exp \left(a_{i}\left(z \theta_{v}-b_{i z}\right)\right)} \tag{6.3}
\end{equation*}
$$

assuming a response variable with $m_{i}+1$ ordered categories. Very often, the threshold parameters are split into a location and normalized step parameters, $b_{i x}=\delta_{i}-\tau_{i x}$, with $\Sigma_{x} \tau_{i x}=0$.

The proficiency variable $\boldsymbol{\theta}_{\boldsymbol{v}}$ is sometimes assumed to be normally distributed, that is, $\boldsymbol{\theta}_{\boldsymbol{v}} \sim N(\mu, \sigma)$. In TIMSS, a normal distribution is used to obtain initial proficiency estimates, as the 3PL model requires constraints of this and other types for identification (Haberman, 2005; San Martín, González, \& Tuerlinckx, 2015; von Davier, 2009). Subsequently, this normality constraint can be relaxed and other types of distributions utilized (Haberman, von Davier \& Lee, 2008; von Davier \& Sinharay, 2013; von Davier et al. 2006; von Davier \& Yamamoto, 2004; Xu \& von Davier, 2008).

The following sections address the central assumptions of IRT models such as unidimensionality, conditional independence and monotonicity of item-proficiency regressions.

### 6.4 Unidimensionality

Large-scale assessments measure students' achievement on several items they receive. Let $I$ denote the number of items and let the response variables be denoted by $x=\left(x_{1}, \ldots, x_{I}\right)$. Unidimensionality means that a single quantity is sufficient to describe the probabilities of these responses to each of the items and that this quantity is the same regardless of the selection of items a student received from within an assessment domain. Denote $P_{i v}$ and $P_{j v}$ as the probability of person $v$ scoring 1 on items $i$ and $j$.

$$
\begin{equation*}
P_{i v}=P_{i}\left(X=1 \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right) \tag{6.4}
\end{equation*}
$$

and

$$
\begin{equation*}
P_{j v}=P_{j}\left(X=1 \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right) \tag{6.5}
\end{equation*}
$$

with the same real-valued $\boldsymbol{\theta}_{\boldsymbol{v}}$ in each expression. Unidimensionality ensures that the same underlying proficiency is measured by all the test items in the domain. This of course holds only if the assessment development aims at producing a set of items that are indeed designed to assess the same assessment domain and that test developers diligently refer to the content specifications outlined in the assessment framework.

### 6.5 Conditional Independence

The assumption of population independence states that the probabilities of producing a correct response for a given level of proficiency are not dependent on the group to which a test taker belongs. In international large-scale assessments, this independence is important for inferences across countries, but also within countries for inferences across different student groups. Formally population independence holds if

$$
\begin{equation*}
P\left(X_{i}=x_{i} \mid \theta, g\right)=P\left(X_{i}=x_{i} \mid \theta\right) \tag{6.6}
\end{equation*}
$$

for any contextual variable $g$. This also holds for groups defined by performance on $x_{j}$ on items $j<i$ that precede the current item response $x_{i}$. The response to a preceding item can be considered a grouping variable as well, as it splits the sample into those that produced a correct response and those who did not, in the simplest case. Applying the assumption of population independence, this yields

$$
\begin{equation*}
P\left(x_{i}, x_{j} \mid \theta\right)=P\left(x_{i} \mid x_{j}, \theta\right) P\left(x_{j} \mid \theta\right)=P\left(x_{i} \mid \theta\right) P\left(x_{j} \mid \theta\right) \tag{6.7}
\end{equation*}
$$

The assumption of local independence directly follows. It states that the joint probability of observing a series of responses, given a student's proficiency level $\theta$, can be written as the product of the item level probabilities. For a set of responses, local independence takes the form

$$
\begin{equation*}
P\left(\mathrm{X}=x_{1}, \ldots, x_{I} \mid \theta\right)=\prod_{i=1}^{I} P_{i}(X=1 \mid \theta)^{x_{i}}\left[1-P_{i}(X=1 \mid \theta)^{1-x_{i}}\right. \tag{6.8}
\end{equation*}
$$

According to the assumption of population invariance and local independence, if the model fits the data (and, for example, no learning occurs) and only one single proficiency is 'responsible' for the probability of giving correct responses, then no other variables (including language of the assessment, citizenship, gender, and other contextual variables) are helpful in predicting a respondent's answer to the next item. In this sense, the assumption of local independence and population invariance encapsulate the goal that there is only one variable that needs to be considered and that estimates of this variable will fully represent the available information about proficiency.

### 6.6 Monotonicity of Item-Proficiency Regressions

One important assumption of IRT models used for achievement data is the (strict) monotonicity of item functions. As seen in Exhibit 11.1, the Rasch model (but also the 2PL and 3PL IRT models) assumes that the probability of a correct response increases with increasing proficiency.

## Exhibit 6.1: Example Item Characteristic Curve

This is represented in the following inequality

$$
\begin{equation*}
P\left(X_{i}=1 \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right)<P\left(X_{i}=1 \mid \boldsymbol{\theta}_{\boldsymbol{w}}\right) \longleftrightarrow \boldsymbol{\theta}_{\boldsymbol{v}}<\boldsymbol{\theta}_{\boldsymbol{w}} \tag{6.9}
\end{equation*}
$$

for all items $i$. This assumption ensures that the proficiency 'orders' the success on the items the students receive and implies that students with a higher level of proficiency will also have a higher probability of success on each of the items in the achievement domain. By implication, there is also a strict monotonic relationship between the expected achievement scores and proficiency $\theta$ :

$$
\begin{equation*}
E\left(S \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right)=\sum_{i=1}^{I} P\left(X_{i}=1 \mid \boldsymbol{\theta}_{\boldsymbol{v}}\right)<E\left(S \mid \boldsymbol{\theta}_{\boldsymbol{w}}\right)=\sum_{i=1}^{I} P\left(X_{i}=1 \mid \boldsymbol{\theta}_{\boldsymbol{w}}\right) \longleftrightarrow \boldsymbol{\theta}_{\boldsymbol{v}}<\boldsymbol{\theta}_{\boldsymbol{w}} \tag{6.10}
\end{equation*}
$$

The equation above shows that a person with a greater skill level $\boldsymbol{\theta}_{\boldsymbol{w}}$ compared to a lesser skill level $\boldsymbol{\theta}_{\boldsymbol{v}}$ will in terms of expected score $E\left(S \mid \boldsymbol{\theta}_{\boldsymbol{w}}\right)$ obtain a larger number of correct responses. This monotonicity ensures that the items and test-takers are ordered as one would expect, namely that higher levels of proficiency are associated with higher expected achievement - a larger expected number of observed
correct responses - for any given item or item block measuring the same domain in an assessment booklet.

### 6.7 Multidimensional IRT Models

In multidimensional IRT (MIRT) models, the model can be specified for multiple scales. It is assumed that the IRT holds, with the qualifying condition that it holds with one or more ability parameters for each of a set of distinguishable subsets (scales) of items (Reckase, 2009; von Davier, Rost, and Carstensen 2007). For the case of a multidimensional 2PL, for example, with between-item multidimensionality (each item loads on only one scale), the probability of response ( $X_{i v}=1$ ) to item $i$ in scale $k$ by respondent $v$ can be defined as:

$$
\begin{equation*}
P\left(x_{i v}=1 \mid \boldsymbol{\theta}_{\boldsymbol{v}}, \beta_{i}, \alpha_{i}\right)=\frac{\exp \left[\sum_{\mathrm{k}=1}^{K} \alpha_{i k}\left(x_{i v} \theta_{v k}-\beta_{i}\right)\right]}{1+\exp \left[\sum_{\mathrm{k}=1}^{K} \alpha_{i k}\left(x_{i v} \theta_{v k}-\beta_{i}\right)\right]} \tag{6.11}
\end{equation*}
$$

where $\boldsymbol{\theta}_{\boldsymbol{v}}$ is a vector of latent variables and $\alpha_{i}$ is a vector of the item loadings for item $i$ on scale $k$ with the restriction that each item loads on only one scale. Unidimensional IRT models used in our analysis may be treated as special case of MIRT where $\boldsymbol{\theta}_{\boldsymbol{v}}=\theta_{v}$ that is one latent dimension is assumed $(K=1)$.

The following section will describe how the IRT models illustrated above were applied to the Rosetta Stone study data to estimate item parameters and to examine their cross-country and cross-assessment invariance.

## 7. IRT Model Application to PASEC and Rosetta Stone Data

This section describes the application of IRT scaling to Rosetta Stone linking items in particular as well as the PASEC item re-calibration performed by the TIMSS \& PIRLS International Study Center. An overview of the specific model applications, and the examination of item-by-country interactions are followed by the results for Rosetta Stone linking and PASEC items.

### 7.1 Establishing Comparability through IRT Scaling

The comparability across assessments and countries for the Rosetta Stone linking items was evaluated by fixing the parameters to the published TIMSS and PIRLS item parameters for all three countries. More precisely, the item parameters used came from the TIMSS 2019 less difficult IRT calibration and the PIRLS Literacy 2016 IRT calibration (both assessments were linked to TIMSS and PIRLS) and were estimated based on the 2PL, 3PL and GPCM (Martin, von Davier \& Mullis, 2020). The comparability of the PASEC items across countries was evaluated by estimating common item parameters across countries based on the Rasch model, in accordance with PASEC analysis procedures (PASEC, 2020). All IRT models
were applied as multiple group models with countries as groups and estimated using the open-source package mirt (Chalmers, 2012) available in the R statistical programming language ( R Core Team, 2013).

Separate unidimensional multiple group IRT models (with countries as groups) were estimated for each assessment domain resulting in four models:

- Model 1 (M1) was estimated for the 105 TIMSS numeracy items.
- Model 2 (M2) was estimated for the 62 PIRLS literacy items.
- Model 3 (M3) was estimated for the 84 PASEC mathematics items.
- Model 4 (M4) was estimated for the 98 PASEC reading items.

While M1 and M2 use the published TIMSS and PIRLS item parameters as fixed values, item parameters for M3 and M4 were estimated. In a first step, common item parameters were assumed across countries in each model. The fit of these common parameters was examined for all item-by-country combinations. That is, item-by-country interactions were examined as a possible result of differential item functioning (DIF). To set the scale, a reference group constraint was used when all item parameters were estimated in the model (M3 and M4) while no reference group constraint was used if item parameters were fixed in the model (M1 and M2).

Item-level model-fit analyses are a critical part of the scaling analyses described above. Different types of DIF statistics can be used to evaluate the extent to which the IRT model applied to a group fits the response data collected from that group. In the context of the IRT models used in the Rosetta Stone study, item-level model fit was examined using a robust approach to identifying misfit (von Davier \& Bezirhan, 2021) based on the root mean squared deviation (RMSD).

The RMSD quantifies the extent to which the model-based item characteristic curve (ICC; computed using equations 6.2 or 6.3) and the empirical ICC can differ with regard to both the item difficulty parameters and item slope parameters. The ICC characterizes the relationship between a person and item parameters. The RMSD is defined as:

$$
\begin{equation*}
R M S D=\sqrt{\int\left(P_{o}(\theta)-P_{e}(\theta)\right)^{2} f(\theta) d \theta} \tag{7.1}
\end{equation*}
$$

where $P_{o}(\theta)$ and $P_{e}(\theta)$ are the observed and expected probability of a correct response given proficiency $\theta$; and $f(\theta)$ is the country-specific density (Khorramdel, Shin, \& von Davier, 2019; von Davier, 2005). The observed probability correct is based on the pseudo counts from the EM algorithm that is used to estimate the model (Bock \& Aitkin, 1981), while the expected probability correct is based on the estimated item function.

The median absolute deviation (MAD) is a robust measure of dispersion which can be used as a flagging rule to detect misfitting items. MAD classifies an observation as an outlier if the difference
to the median of the absolute distances of all other observations exceeds a certain boundary. MAD is calculated as:

$$
\begin{equation*}
M A D=b M_{i}\left(\left|x_{i}-M_{j}\left(x_{j}\right)\right|\right) \tag{7.2}
\end{equation*}
$$

where, $x_{j}$ is the $n$ original observations and $M_{i}$ is the median of the series (Leys et al., 2013). b is the reciprocal of 0.75 quantiles of the underlying distribution. Under the assumption of normality of the data $b=1 / Q(0.75)=1.4826$. A threshold $(k)$ should be defined to identify the misfitting observations. Then we can write the decision criterion as:

$$
\begin{equation*}
\frac{x_{i}-M}{M A D}>| \pm k| \tag{7.3}
\end{equation*}
$$

In the Rosetta Stone scaling, the MAD outlier detection approach was applied to the RMSD values for all country-by-item combinations to identify misfitting items. Any value obtained in (7.3) exceeding a threshold of 1.96 was flagged as an outlier of the RMSD distribution (i.e., as misfitting item).

Item misfit relative to the TIMSS and PIRLS item parameters in M1 and M2 indicates that item characteristics (such as item difficulty and discrimination) differ across the data collections. In such cases, new common item parameters were estimated across countries and the item fit was evaluated again. Item misfit to new common item parameters in M1, M2, M3, and M4 indicates that item characteristics differ across PASEC countries. In such cases, items were excluded from the scaling.

After PASEC and Rosetta Stone items were scaled with separate unidimensional IRT models, multidimensional IRT models were used to examine how similar or different the measured constructs of the different assessments are. More precisely, the latent correlations from the multidimensional models were used to investigate the relationship between the PASEC mathematics and TIMSS numeracy scales and between the PASEC reading and PIRLS literacy scales. Hence, the following 2-dimensional IRT models were estimated:

- Model 5 (M5) was estimated with the PASEC mathematics items assigned to one factor/scale and TIMSS items assigned to a second factor/scale.
- Model 6 (M6) was estimated with the PASEC reading items assigned to one factor/scale and PIRLS items assigned to a second factor/scale.

The item parameters in M5 were fixed to the item parameter values obtained from M1 and M3, while the item parameters in M6 were fixed to the item parameter values in M2 and M4.

To establish a meaningful concordance between the PASEC scales and the TIMSS or PIRLS scales, these need to measure highly similar constructs, which is evaluated by means of the magnitude of the latent correlations estimated in models M5 and M6.

### 7.2 Results for Unidimensional IRT Models

The unidimensional IRT models showed high levels of comparability across countries and across assessments for the Rosetta Stone scales (M1, M2) and across countries for PASEC scales (M3, M4) providing a solid basis for establishing a concordance. The tables in Exhibits 7.1 and 7.2 show the percentages of common (fixed and new) and excluded item parameters for all item-by-country combinations in each of the unidimensional IRT models.

Results for M1 and M2 showed high levels of agreement of item functioning across countries and assessments. In M1 and M2, the TIMSS numeracy and PIRLS literacy item parameters showed a good fit for the majority of item-by-country pairs ( $86.3 \%$ and $81.2 \%$ respectively). For a very small subset of items, new common item parameters needed to be estimated ( $12.4 \%$ and $8.1 \%$ for numeracy and literacy respectively) which, therefore, do not serve as link items to the TIMSS and PIRLS scales but are still comparable across Rosetta Stone countries. In some cases of item-by-country pairs, items needed to be excluded from the analysis ( $1.3 \%$ and $10.7 \%$ for numeracy and literacy, respectively); items were either excluded for all or for single countries.

Results for M3 and M4 showed high levels of agreement of item functioning across countries as well. In the vast majority of item-by-country pairs for the PASEC mathematics and PASEC reading items, a good fit to the common item parameter estimates was achieved ( $92.5 \%$ and $91.5 \%$ respectively). In a very small number of cases of item-by-country pairs, items needed to be excluded from the analysis (7.5\% and $8.5 \%$ for mathematics and reading respectively); again, items were either excluded for all or single countries.

Exhibit 7.1: Percentages of Item Parameter Estimates for Item-by-Country Combinations (Pairs) in Model 1 and Model 2

| Item Parameters | TIMSS-Numeracy <br> (Model 1) | PIRLS-Literacy <br> (Model 2) |
| :--- | :---: | :---: |
| Fixed | $86.3 \%$ | $81.2 \%$ |
| New Common | $12.4 \%$ | $8.1 \%$ |
| Excluded | $1.3 \%$ | $10.7 \%$ |

Exhibit 7.2: Percentages of Item Parameter Estimates for Item-by-Country Combinations (Pairs) in Model 3 and Model 4

| Item Parameters | PASEC Math <br> (Model 3) | PASEC Reading <br> (Model 4) |
| :--- | :---: | :---: |
| Common | $92.5 \%$ | $91.5 \%$ |
| Excluded | $7.5 \%$ | $8.5 \%$ |

A graphical overview of the proportions of fixed and common (invariant) item parameters and excluded items in each domain is given in the figures in Exhibits 7.3 to 7.6. In Exhibits 7.3. and 7.4, dark green indicates the fixed TIMSS and PIRLS item parameters (common item parameters across assessments), light green indicates new common item parameters (common across PASEC countries), and orange indicates excluded items for specific item-by-country pairs. In Exhibits 7.5 and 7.6, dark green indicates common item parameter estimates (common across PASEC countries) and orange indicates excluded items for specific item-by-country pairs. Note that item parameters were ordered for visualization purposes and that the grouping of colors in the figures does not indicate any specific pattern. No particular pattern could be observed for item-by-country interactions with regard to item type or content.

## Exhibit 7.3: Distribution of Model 1 Items with Common Item Parameters versus Excluded Items

Exhibit 7.4: Distribution of Model 2 Items with Common Item Parameters versus Excluded Items

Exhibit 7.5: Distribution of Model 3 Items with Common Item Parameters versus Excluded Items

Exhibit 7.6: Distribution of Model 4 Items with Common Item Parameters versus Excluded Items

Given the small number of PASEC countries participating in Rosetta Stone and the smaller sample sizes in each country compared to customary TIMSS and PIRLS samples, the uncertainty in the estimation of common item parameters in M3 and M4 needed to be examined. That is, the effects of single countries on the item parameter estimation. This was done by conducting and comparing different rounds of item parameter estimation, separately for M3 and M4, using the leave one "country" out (LOO) method. More precisely, M3 and M4 were estimated by leaving one country out at a time of the estimation in each iteration. To obtain the final estimates from the calibrations, item parameters were pooled, and variability was estimated. Exhibits 7.7 and 7.8 illustrate the Rasch model-based item difficulties for M3 and M4 for the different estimation rounds: the colored lines indicate the estimates for each round with one country left out at a time while the black dots indicate the mean difficulties across all estimation rounds and the
related mean standard errors as indicated by the intervals. Note that items in both figures were ordered by difficulty for visualization purposes.

Overall, mathematics items (M3) estimates show larger variability compared to the reading items (M4). For LOO with M3, it was also observed that when Burundi was left out of the estimation, difficulty estimates were consistently larger for mathematics items compared to when either Senegal or Guinea was left out. For LOO with M4, no clear pattern was observed for the item parameter estimation. Overall, the effect of a single country on item parameter estimates was minimal, especially for PASEC reading items.

## Exhibit 7.7: Rasch Model-Based Item Difficulties for LOO Estimation Rounds Model 3 (PASEC Mathematics)

Exhibit 7.8: Rasch Model-Based Item Difficulties for LOO Estimation Rounds Model 4 (PASEC Reading)

### 7.3 Results for Multidimensional IRT Models

The 2-dimensional IRT models (M5 and M6) provided information about the relation and similarity of the different constructs. The latent correlations between dimensions in both 2-dimensional IRT models showed to be substantial but not perfect ranging from .81 to .86 across countries in M5, and from .78 to .83 across countries in M6, see exhibit 7.9. This indicates that the corresponding Rosetta Stone and PASEC scales measure constructs that are not the same but similar enough to enable a meaningful concordance for the projection of score distributions.

Exhibit 7.9: Latent Correlations between PASEC and Rosetta Stone Scales

| Country | PASEC Mathematics <br> with TIMSS (M5) | PASEC Reading <br> with PIRLS (M6) |
| :--- | :---: | :---: |
| Burundi | .81 | .78 |
| Guinea | .81 | .79 |
| Senegal | .86 | .83 |

## 8. Population Models

Section 8 describes the general principles followed for the population modeling and the imputation of plausible values ( PVs ).

### 8.1 Integrating Achievement Data and Context Information

Rosetta Stone uses a latent regression or population model to estimate distributions of proficiencies. The population model is based on the likelihood function of an IRT model, as introduced in section 6 of this report, and a linear, latent regression of the proficiency on contextual data collected in background or context questionnaires (von Davier et al., 2006; von Davier et al., 2009). This approach can be viewed as an imputation model for the unobserved proficiency distribution that aims at obtaining unbiased group-level proficiency distributions by utilizing information about the extent to which background or context variables are related to the proficiency variable. Population models use a large number of context variables in the latent regression to avoid the omission of any useful information (von Davier et al., 2006; von Davier et al., 2009; von Davier \& Sinharay, 2013).

To reduce the number of context variables and avoid overparameterization, a principal component analysis (PCA) is used to eliminate collinearity by identifying a smaller number of orthogonal predictors that account for most of the variation in the background variables.

To facilitate the estimation procedure, the data from the context questionnaires are combined with the responses obtained from the achievement items. The complete observed data for a person $n$ can be expressed as $d_{n}=\left(x_{n 1}, \ldots, x_{n 1}, g_{n}, z_{n 1}, \ldots, z_{n B}\right)$, where $z_{n 1}, \ldots, z_{n B}$ represent the context information, $x_{n 1}, \ldots$,
$x_{n I}$ represent the answers to the achievement items, and $g_{n}$ represents the country or population the respondent was sampled from.

The estimation of student-level posterior proficiency distributions with IRT models utilizes an estimate of the proficiency distributions in the population of interest. A population model that incorporates contextual data utilizes this information by specifying a second-level model that predicts the distribution of proficiency as a function of contextual variables. The conditional expectation in this model is given by

$$
\begin{equation*}
\mu_{n}=\sum_{b=1}^{B} \beta_{g(n) b} z_{n b}+\beta_{g(n) 0} \tag{8.1}
\end{equation*}
$$

This expectation uses the available information on how context variables relate to the proficiency. The distribution of proficiency is assumed to be normally distributed around this conditional expectation, namely $\boldsymbol{\theta}_{\boldsymbol{n}} \sim N\left(\mu_{n}, \sigma\right)$.

Together with the likelihood of the responses expressed by the IRT model, this provides a model for the posterior distribution of proficiency given the context data $z_{n 1}, \ldots, z_{n B}$ and the responses to the items. In other words, the model implements the assumption that the posterior distribution of proficiency depends on the context data as well as on the observed item responses. Therefore, if background variables are selected so that correlations with proficiency are likely, one obtains a distribution around the expected value given the conditional expectation in (8.1) that is noticeably more accurate than a country-level distribution of proficiency.

### 8.2 Group-Level Proficiency Distributions and Plausible Values

The goal of population modeling is to produce posterior distributions of proficiencies from which plausible values (PVs) can be drawn. Integrating the IRT models described in section 7 of this report with the regression model introduced at the beginning of this section, we can estimate the probability of the responses, conditional on context information, as

$$
\begin{equation*}
P_{g}\left(x_{n} \mid z_{n}\right)=\int_{\theta} \prod_{i=1}^{I} P_{i g}\left(x_{n i} \mid \theta\right) \Phi\left(\theta ; \sum_{b=1}^{B} \beta_{g b} z_{n b}+\beta_{g 0}, \sigma\right) d \theta \tag{8.2}
\end{equation*}
$$

This equation provides the basis for the imputation of proficiency estimates that are commonly known as PVs (Mislevy, 1991). To allow a more compact notation, we use

$$
\begin{equation*}
P_{i g}\left(x_{n i} \mid \theta\right)=P_{i g}(X=1 \mid \theta)^{x_{n i}}\left[1-P_{i g}(X=1 \mid \theta)\right]^{1-x_{n i}} \tag{8.3}
\end{equation*}
$$

The model given in 8.2 enables inferences about the posterior distribution of the proficiency $\theta$, given both the TIMSS assessment items $x_{1}, \ldots, x_{I}$ and the context information $z_{1}, \ldots, z_{B}$. The posterior distribution of the proficiency given the observed data can be written as

$$
\begin{equation*}
P_{g}\left(\theta \mid x_{v}, z_{n}\right)=\frac{\prod_{i=1}^{I} P_{i g}\left(x_{n i} \mid \theta\right) \Phi\left(\theta ; \sum_{b=1}^{B} \beta_{g b} z_{n b}+\beta_{g 0}, \sigma\right)}{\int_{\theta} \prod_{i=1}^{I} P_{i g}\left(x_{n i} \mid \theta\right) \Phi\left(\theta ; \sum_{b=1}^{B} \beta_{g b} z_{n b}+\beta_{g 0}, \sigma\right) d \theta} \tag{8.4}
\end{equation*}
$$

An estimate of where a respondent n is most likely located on the proficiency dimension can be obtained by

$$
\begin{equation*}
E_{g}\left(\theta \mid x_{n}, z_{n}\right)=\int_{\theta} \theta P_{g}\left(\theta \mid x_{n}, z_{n}\right)=d \theta \tag{8.5}
\end{equation*}
$$

The posterior variance, which provides a measure of uncertainty around this expectation, is calculated as follows:

$$
\begin{equation*}
V_{g}\left(\theta \mid x_{n}, z_{n}\right)=E_{g}\left(\theta^{2} \mid x_{n}, z_{n}\right)-\left[E_{g}\left(\theta \mid x_{n}, z_{n}\right)\right]^{2} \tag{8.6}
\end{equation*}
$$

Using these two estimates (the posterior mean and variance) to define the posterior proficiency distribution, it is possible to draw a set of PVs from this distribution for each student. PVs are the basis for all reporting of proficiency data in large-scale assessments such as TIMSS, PIRLS or PASEC, allowing reliable group-level comparisons.

Note that the correlations between context variables and proficiency are estimated separately in each country so that there is no bias or inaccurate attribution that could affect the results. Although the expected value of the country-level proficiency is unchanged whether context information is used or not, the advantage of including context information plays out when making group-level comparisons. It can be shown analytically and by simulation (von Davier et al., 2009) that including context information in a population model greatly reduces bias in group-level comparisons using this information, and using country-specific population models with context variables ensures there is no bias in country-level average proficiency data.

In summary, the PVs used in TIMSS, PIRLS, PASEC, and other large-scale assessments are random draws from a conditional normal distribution

$$
\begin{equation*}
\tilde{\theta}_{n g} \sim N\left(E_{g}\left(\theta \mid x_{n}, z_{n} \sqrt{V_{g}\left(\theta \mid x_{n}, z_{n}\right)}\right)\right. \tag{8.7}
\end{equation*}
$$

that depends on response data $x_{n}$ as well as context information $z_{n}$ estimated using a group-specific model for each country $g$. That means two respondents with the same item responses, but different context information will receive a different predicted distribution of their corresponding latent trait. Although this may seem potentially unfair to individual test takers - and would not be adequate to assign test scores to individual students - it is important to remember that large-scale assessments are
population surveys, not individual assessments, and that it is necessary to include context information in order to achieve unbiased comparisons of population distributions (e.g., Little \& Rubin, 1987; Mislevy, 1991; Mislevy et al., 1992; Mislevy \& Sheehan, 1987; von Davier et al., 2009). Consequently, PVs are not and should never be used or treated as individual test scores.

## 9. Population Model Application to PASEC and Rosetta Stone Data

Section 9 describes the application of population models in Rosetta Stone specifically as well as the replication of PASEC PVs for validation purposes.

### 9.1 Applied Population Models

The population model, as described above, is a multivariate model that incorporates the available student context variables from the PASEC student questionnaire, as well as the Rosetta Stone linking item parameters and the PASEC item parameters from the IRT scaling, respectively.

For Rosetta Stone, two 2-dimensional models were used:

- Population Model 1: was estimated for TIMSS numeracy and PIRLS literacy
- Population Model 2: was estimated for PASEC math and PASEC reading

Population Model 1 follows the practice established by TIMSS and PIRLS of using principal components analysis for reducing collinearity and dimensionality of predictors while retaining $90 \%$ of their common variance. It was calculated separately for each of the three countries that participated in the Rosetta Stone study. Latent regression parameters were estimated while the item parameters obtained from the IRT scaling (described in section 7) were assumed to be fixed and known.

In addition to the principal components, students' gender (dummy coded) and an indicator of the classroom in the school to which a student belongs (criterion scaled) were included as primary conditioning variables. Exhibits 9.1 provide details on the counts of variables used in the latent regression used for proficiency estimation of the Rosetta Stone linking data.

Exhibit 9.1: Counts of Conditioning Variables used for the Rosetta Stone Linking Data

| Country | Number of Primary <br> Conditioning <br> Variables | Number of <br> Principal <br> Components <br> Available | Number of <br> Principal <br> Components <br> Retained | Percentage <br> of Variance <br> Explained |
| :--- | :---: | :---: | :---: | :---: |
| Burundi | 2 | 233 | 90 | 90 |
| Guinea | 2 | 234 | 89 | 90 |
| Senegal | 2 | 234 | 103 | 90 |

The same analysis steps and conditioning variables were used for Population Model 2. Note that this model was only estimated for evaluation purposes and is, therefore, not described in detail here. The PASEC PVs that were provided by the PASEC team were used for constructing the concordance tables after the validity could be confirmed based on the results of Population Model 2.

### 9.2 Generating Plausible Values and PASEC Score Validation

Educational Testing Service's DGROUP program (Rogers et al., 2006) was used to estimate the latent regression models and generate PVs. A useful feature of DGROUP is its ability to estimate multidimensional latent regression models using the responses to all items across the proficiency scales and the correlations among the scales to improve the reliability of estimates (e.g., von Davier, Sinharay, Oranje \& Beaton, 2006).

Following the procedures in TIMSS and PIRLS (Foy, Fishbein, von Davier, \& Yin, 2020; Foy \& Yin, 2017), five PVs were drawn from the conditional distribution for each domain and each student. A predictive distribution of PVs was produced for the TIMSS numeracy and the PIRLS literacy domains (Population Model 1) as well as for the PASEC mathematics and reading domains (Population Model 2).

The PASEC PVs received from the PASEC team were evaluated in two steps. First, the distributions for PASEC scales based on these PVs were compared to the PASEC 2019 published results. Exhibits 9.2 and 9.3 show that both sets of results are very similar indicating that the Rosetta Stone student sample is comparable to the PASEC 2019 student sample. The standard errors (SEs) for the 2019 published results generally are smaller than SEs for the Rosetta Stone sample because they were estimated based on larger national samples.

Second, they were compared to the re-estimated PVs from Population Model 2. Very high correlations between both sets of PVs could be observed (ranging from .95 to .97 , and from .96 to .98 for mathematics and reading respectively) indicating very good agreement of analytic processes.

Exhibit 9.2: Comparison of Published (2019) and Rosetta Stone Study Results for PASEC Scales

### 9.3 Transforming the Plausible Values to TIMSS and PIRLS Scales

The numeric scales of the PVs that were drawn using the model parameters of each population model were set by means of the IRT scaling and had to be transformed to the TIMSS and PIRLS reporting metric. This was accomplished through a set of linear transformations given by:

$$
\begin{equation*}
P V^{*}=A_{i k}+B_{i k} \times P V_{i k} \tag{9.1}
\end{equation*}
$$

Where $\boldsymbol{P} V_{i k}$ is the plausible value $i$ of scale $k$ (mathematics or reading) prior to transformation; $\boldsymbol{P} \boldsymbol{V}^{*}{ }_{i k}$ is the plausible value $i$ of scale $k$ after transformation; and $\boldsymbol{A}_{\boldsymbol{i k}}$ and $\boldsymbol{B}_{\boldsymbol{i k}}$ are the linear transformation constants.

For the Rosetta Stone linking data, the linear transformation constants for numeracy and literacy were obtained from TIMSS 2019 less difficult (Foy et al., 2020) and PIRLS Literacy 2016 (Foy and Yin, 2016). There are five sets of transformation constants for each scale or subject, one for each plausible value (Exhibit 9.4).

Exhibit 9.4: Transformation Constants for Rosetta Stone (TIMSS and PIRLS) Linking Data

| Plausible Value (PV) |  | TlMSS |  | PIRLS |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | A | B | A | B |  |
| PV1 | 404.448 | 113.863 | 516.968 | 96.598 |  |
| PV2 | 404.156 | 113.749 | 516.163 | 97.544 |  |
| PV3 | 405.574 | 112.539 | 515.765 | 97.534 |  |
| PV4 | 404.177 | 114.003 | 515.905 | 97.571 |  |
| PV5 | 403.994 | 114.170 | 516.014 | 97.267 |  |

The following two sections describe how posterior means and PVs produced for Rosetta Stone data were used to establish concordance tables for PASEC mathematics and TIMSS numeracy as well as for PASEC reading and PIRLS literacy.

## 10. Establishing an Enhanced Concordance between Scales

Scale concordance refers to establishing a relationship between scores on different assessments or tests that measure similar (but not identical) constructs. It aims to provide a projection onto a target scale score from a source scale score. In Rosetta Stone, a range of TIMSS and PIRLS scores is predicted or projected from PASEC mathematics and reading scores respectively. That is, PASEC mathematics and PASEC reading represent the source test $\theta$ and TIMSS and PIRLS represent the target test 9 . This prediction can be displayed as a concordance table and provide useful information to stakeholders, researchers, or institutions who need to compare test scores.

A technically sound concordance allows students and professionals to compare scores from similar assessments to inform decisions. However, concorded scores are not true predictions of how students would perform on the other test as they do not provide a direct link between tests. While predictions or equating of scores includes uncertainty due to measurement error, concordance-based projections include an additional source of uncertainty, the error due to projecting from one construct to another. In addition, concordance tables are dependent on the characteristics of the sample and include uncertainty due to sampling. Hence, the uncertainty of the prediction has to be taken into consideration when using and interpreting concordance tables.

The method used for establishing scale concordance in the Rosetta Stone study directly takes the uncertainty of the proficiency estimates on source and target test forms into account and thus appropriately controls for potential construct differences between the tests. More specifically, the proposed method is based on predictive mean matching (PMM; Little, 1988; Rubin, 1986) as well as imputation methodology (PVs). It provides a method for score projections where equating methods are not defensible as they would make unrealistic assumptions such as equivalency of constructs and reliability levels.

### 10.1 Predictive Mean Matching (PMM)

Predictive mean matching (PMM) (Little, 1988; Rubin, 1986) finds a small number of 'donor' observations based on a predicted value generated by an imputation model. Assume that a number of observed variables is available as a predictor set $Z_{1}, \ldots, Z_{K}$ and that an imputation model was specified to predict the conditional distribution of a variable $\theta$ so that we can write the predictive distribution as

$$
\begin{equation*}
\Phi_{z}(\theta)=P\left(\theta \mid Z_{1 v}, \ldots, Z_{K}\right) \tag{10.1}
\end{equation*}
$$

PMM replaces a missing observation $\boldsymbol{\theta}_{\boldsymbol{v}}$ of a respondent $v$ by defining the predictive mean of this respondent as

$$
\begin{equation*}
\hat{\boldsymbol{\theta}}_{\boldsymbol{v}}=E\left(\theta \mid Z_{1 v}, \ldots, Z_{K v}\right) \tag{10.2}
\end{equation*}
$$

finding a small number of 'donor' observations by selecting these. $m_{1 v}=m_{1}\left(\hat{\boldsymbol{\theta}}_{v}\right), \ldots, \mathrm{m}_{L v}=\mathrm{m}_{L}\left(\hat{\boldsymbol{\theta}}_{v}\right)$ based on their distance to $\hat{\theta}_{v}$. That is, the goal is to find the set of $L$ donors with the smallest distances to the predicted mean so that

$$
\begin{gather*}
\left|\boldsymbol{\theta}_{\boldsymbol{m}}-\hat{\boldsymbol{\theta}}_{\boldsymbol{v}}\right| \text { for } m \in\left\{m_{1 v}, \ldots, m_{L v}\right\}<\left|\boldsymbol{\theta}_{m}-\hat{\boldsymbol{\theta}}_{\boldsymbol{v}}\right| \text { for } m  \tag{10.3}\\
\in\{1, \ldots, N\} \backslash\left\{m_{1 v}, \ldots, m_{L v}\right\}
\end{gather*}
$$

This can simply be achieved by sorting all observations according to this distance and choosing the $L$ observations with the smallest differences. Finally, these closest observations

$$
\begin{equation*}
\left\{\theta_{m_{1 v}}, \ldots, \theta_{m_{L v}}\right\} \tag{10.4}
\end{equation*}
$$

are taken as the imputed values for the missing observation $\boldsymbol{\theta}_{\boldsymbol{\gamma}}$.
The advantage of PMM over other methods of imputation can be described as the 'realism' in the imputed values. The predicted mean given in equation (10.2) can be out of range, say if a constrained range sum score on a test is imputed, while the imputed (donated) set of values given in (10.4) is not only guaranteed to be within range, but also to follow other features of the observed distribution. For example, if the sum score is discrete, either if classical test theory (CTT) or a Rasch model was used, the donated values will be discrete scores as well, while the predicted conditional means, and the draws from the posterior used for imputation will, in general, not be discrete. Or, if the 'true' observed distribution is censored, skewed, or bimodal, the donated values will mimic these features, while this is typically not the case when using a parametric form for the posterior distribution selected for generating imputations.

### 10.2 Technical Procedure for Establishing Concordance Tables

The technical procedures described in this section draw on the statistical principles of conditioning models used in PASEC, TIMSS and PIRLS, (e.g., von Davier, Gonzalez \& Mislevy, 2009; von Davier \& Sinharay, 2013). This allows constructing a concordance enhanced by conditional variance estimates to properly account for uncertainty and can be described as follows:

1. The predictive means of source test score $\theta$ and target test score $\vartheta$ are derived utilizing population models as described in the previous sections 8 and 9 . The expected value given responses and context is given by

$$
\begin{equation*}
\hat{\vartheta}=E\left(\vartheta \mid Y_{1}, \ldots, Y_{J}, Z_{1}, \ldots, Z_{K}\right) \text { and } \hat{\theta}=E\left(\theta \mid X_{1}, \ldots, X_{I}, Z_{1}, \ldots, Z_{K}\right) \tag{10.5}
\end{equation*}
$$

2. The conditional distribution is available for generating imputations for $\vartheta$ for those cases where only test $X_{1}, \ldots, X_{I}$ is given together with the context variables can be constructed if $\vartheta$ is known for a sample, so that the conditional distribution

$$
\begin{equation*}
P\left(\vartheta \mid X_{1}, \ldots, X_{I}, Z_{1}, \ldots, Z_{K}\right) \tag{10.6}
\end{equation*}
$$

becomes available for generating imputations.
3. For a concordance, the full population model using individual responses and context variables is often impractical. Practitioners want to use a score on one test to make inferences about the likely score range on another test. Note this is always projection-based using joint or conditional distributions, and the use of just a point estimate on the target test form given the source test score would be ignoring the uncertainty around this projected score. Therefore, the approach used here utilizes PVs (obtained from population models) to account for the uncertainty of the score projection.
2. The observed joint distribution of source and target test latent variable estimates can be used to create a conditional (predictive) distribution of the target test's latent variable given the source test's variable, $P(\vartheta \mid \theta)$. Based on a sample of respondents $v=1, \ldots, N$, plugging in the posterior means and PVs allows us to approximate this conditional distribution. Instead of the full population model

$$
\begin{equation*}
\hat{\vartheta} \sim P\left(\vartheta \mid X_{1}, \ldots, X_{I}, Z_{1}, \ldots, Z_{K}\right) \tag{10.7}
\end{equation*}
$$

an approximate imputation model $P(\vartheta \mid \theta)$ based on the source and target latent variables only is used and estimated using the two full population models

$$
\begin{equation*}
\hat{\vartheta} \sim E\left(\vartheta \mid Y_{1}, \ldots, Y_{J}, Z_{1}, \ldots, Z_{K}\right) \tag{10.8}
\end{equation*}
$$

and

$$
\begin{equation*}
\bar{\theta} \sim E\left(\theta \mid X_{1}, \ldots, X_{I}, Z_{1}, \ldots, Z_{K}\right) \tag{10.9}
\end{equation*}
$$

to generate an estimate of the conditional distribution

$$
\begin{equation*}
P(\hat{\vartheta} \mid \hat{\theta}) \approx P(\vartheta \mid \theta) \tag{10.10}
\end{equation*}
$$

5. Then, the concordance is essentially given by

$$
\begin{equation*}
P\left(\hat{\vartheta} \mid E\left(\theta \mid X_{1}, \ldots, X_{I}, Z_{1}, \ldots, Z_{K}\right)\right) \tag{10.11}
\end{equation*}
$$

and provides a projected distribution on the target test form given a function of the context variables and observed responses on the source test form.
6. A practical implementation of estimating this concordance can be implemented as:
a. Draw $m=1, \ldots, M$ PVs $\hat{\mathfrak{\vartheta}}_{m n}$ on the target test form for all respondents $n=1, \ldots, N$.
b. Estimate the posterior means

$$
\begin{equation*}
\bar{\theta}_{n}=E\left(\theta \mid X_{1 n}, \ldots, X_{I n}, Z_{1 n}, \ldots, Z_{K n}\right) \tag{10.12}
\end{equation*}
$$

for all respondents $\mathrm{n}=1, \ldots, N$.
c. Select a concordance range of source scores $\Omega=\left\{\theta_{0}<\theta_{1}<\ldots<\theta_{R-1}<\theta_{R}\right\}$ that covers $99 \%$ or more of the $\bar{\theta}$, i.e., so that $\mathrm{P}\left(\theta_{0}<\bar{\theta}<\theta_{R}\right)>0.99$.
d. For each of these concordance table scores $\theta_{r} \in \Omega$, select a set of $L$ donors $d_{1 r}, \ldots, d_{L r}$ that have the smallest distances to the concordance table score $\theta_{r}$. That is $\left|\theta_{m}-\theta_{r}\right|$ for $m \in\left\{d_{1 r}, \ldots, d_{L r}\right\}<\left|\theta_{k}-\theta_{r}\right|$ for $k \in\{1, \ldots, N\} \backslash\left\{m_{1 r}, \ldots, m_{L r}\right\}$.
e. Use the PVs $\hat{\vartheta}_{1 d_{1 r}}, \ldots, \hat{\vartheta}_{m d_{1 r}}, \hat{\vartheta}_{1 d_{2 r}}, \ldots, \hat{\vartheta}_{m d_{2 r}}, \hat{\vartheta}_{1 d_{L r}}, \ldots, \hat{\vartheta}_{m d_{L r}}$ as the predictive distribution of scores on the target test $\vartheta$ given concordance score $\theta_{r}$.

### 10.3 Advantages of the Enhanced Concordance Method

The enhanced concordance method described above provides an estimate of the conditional distribution $P(\vartheta \mid \theta)$, using imputed scores (PVs) on the target test $\vartheta$, given a model-based point estimate on the source test $\theta$. This model-based point estimate is a posterior mean given the available information of the source test and condenses a complex imputation model for the target test score into a single value that can be used in a concordance table.

The use of PMM finds donors in each sample that are nearest neighbors to the concordance table scores and assigns their target test PVs as the projection of scores based on the closest estimates obtained when only taking the source and target test forms, respectively. This approach ensures that score uncertainty due to measurement error and due to the imperfect correlation between source and target test are appropriately taken into account. In addition, when aggregating multiple population-based concordances, the uncertainty due to variability among countries is appropriately incorporated.

An additional advantage of the approach is that no functional form is assumed for the concordance other than those used to estimate the imputation models for source and target test forms. Commonly used equating and linking methods assume that the construct being measured is the same in source and target test forms, and project a point estimate on the source form onto a point estimate of the target form. Even if a transformed standard error would be used in addition, this would still assume that the constructs are essentially the same. In the proposed method, however, the estimated conditional distribution based on within subject repeated measurement of different tests is used, so that the dependencies (or lack thereof) between source and target test forms are directly incorporated in the enhanced concordance.

Moreover, there is no linearity assumption, and no other functional relationships between source and target test scores assumed other than the one that comes 'naturally' by utilizing multiple donors that are closest neighbors to the concordance table scores. The number of donors and how they are weighted and selected can increase smoothing effects, and the approach followed here uses 5 nearest neighbors per country-specific sample.

## 11. Establishing an Enhanced Concordance between PASEC and TIMSS/PIRLS

This section describes the procedures used to construct the Rosetta Stone concordance tables which provide a projection of the scores on the PASEC source assessment on the scales of the TIMSS and PIRLS target assessments.

### 11.1 Relationship between PASEC data and Rosetta Stone Linking data

As the PASEC mathematics and reading PVs provided by the PASEC team were on the IRT logit metric, they first needed to be transformed to the PASEC reporting metric to make the concordance tables more interpretable and meaningful. This was done by applying the PASEC linear transformation constants. The means of the transformed PASEC PVs for all three countries were compared to the corresponding values in the PASEC 2019 technical report (PASEC, 2020) for quality assurance. Overall, the transformed PASEC PVs were highly consistent with the reported PASEC 2019 scores at the individual country level with mean differences being in the range between 0 to 10 points. Only one country (Guinea) had a slightly larger mean difference between the transformed PASEC mathematics mean and the reported mathematics score in the PASEC 2019 technical report, which is most likely due to sampling variability.

To check the relationship between the data from source and target assessments, the correlations between the posterior means of PASEC data and Rosetta Stone linking data for mathematics/numeracy and reading/literacy were examined. For the PASEC mathematics and reading tests, the posterior means were not available and needed to be approximated. This was done by averaging the five PVs from the PASEC mathematics scale and the five PVs from the PASEC reading scale, respectively. The correlations between the posterior means of PASEC data and Rosetta Stone linking data are presented in the table in Exhibit 11.1.

Exhibit 11.1: Correlations between PASEC Data and TIMSS and PIRLS Linking Data

| Country | PASEC Mathematics <br> with TIMSS | PASEC Reading <br> with PIRLS |
| :--- | :---: | :---: |
| Burundi | 0.73 | 0.73 |
| Guinea | 0.70 | 0.74 |
| Senegal | 0.80 | 0.81 |

Correlations in Exhibit 11.1 approach the latent correlations from the multidimensional IRT models illustrated in section 7.3 and indicate that PASEC and Rosetta Stone scales measure different but similar constructs; that is, correlations are reasonably high for constructing a concordance.

For quality control, the cumulative distributions of the PASEC and the Rosetta Stone posterior means were approximated by averaging the five PVs of the corresponding assessments for each country and are illustrated in Exhibit 11.2. and Exhibit 11.3. Dis-ordinal interactions are shown between the posterior means of PASEC data and Rosetta Stone linking data among the three countries. This finding is consistent with the finding in Exhibit 5.1 and, according to feedback from the participating countries, could potentially be due to curricula differences among countries, and differences between test language and language spoken at home or in the classroom. In addition, the score ranges are quite different across countries which may also contribute to variability of the results across countries.

## Exhibit 11.2: Cumulative Distributions of PASEC Mathematics and TIMSS Linking Data

Exhibit 11.3: Cumulative Distributions of PASEC Reading and PIRLS Linking Data

A joint concordance table was constructed by aggregating the data across countries as country-level differences should not affect projected score averages but be reflected in the variability of projections. As a tool for international comparable assessments, the concordance should form the basis for comparisons regardless of the countries used to construct the projection table. This was done by using PVs for all participating countries in a combined table, one for mathematics and one for reading. Joint concordance tables account for the uncertainty in the measurement (i.e., the measurement error), country-specific effects due to sampling and other nuisance variables, and the imperfect correlation between PASEC data and Rosetta Stone linking data.

### 11.2 Creating Preliminary Concordance Tables

The concordance scores and levels were identified based on estimated PASEC posterior means using the combined data of the three countries. The score ranges of the posterior means of the PASEC mathematics and reading scales were either rounded up or down to cover almost all the data of the three countries and to be as symmetric as possible around the overall mean of the PASEC scale (which is 500). For both PASEC scales, mathematics and reading, scores range from about 200 to 800 (covering almost $100 \%$ of the data) with very few data points beyond the range of 260 to 760 (covering about $99.5 \%$ of the data). Therefore, the following description of creating the concordance tables primarily focusses on the scores within the range from 260 to 760 .

For both PASEC scales, mathematics and reading, 20 points on the PASEC reporting metric were specified as the score interval to include enough score or proficiency levels and to retain as much information as possible. As a result, there are 26 score levels within the score range of 260 to 760 .

For each identified concordance score level, PMM was used to select 5 donors from each of the three countries so that each country contributes equally to each of the concordance tables. Each of the donors donated 5 PVs on the target tests. This selection was achieved by selecting the 5 smallest absolute differences of students' posterior mean on the PASEC test to each specified concordance score for each country. The mean and standard deviation of the donors' PVs from the Rosetta Stone linking data were calculated based on the total 75 donated PVs ( 3 countries $\times 5$ donors $\times 5 \mathrm{PVs}$ ) at each concordance level. Note that these steps were implemented separately for PASEC mathematics and reading.

Preliminary concordance tables for PASEC mathematics and PASEC reading were created by assigning the estimated mean and standard deviation of each set of 75 PVs based on the TIMSS and PIRLS linking data, respectively, to each concordance score level in the specified range of PASEC mathematics and PASEC reading.

### 11.3 Smoothing and Extrapolating the Concordance Tables

To examine the distribution of the donated PVs on the target tests, boxplots of each set of 75 donated PVs were produced for each concordance score level between the range of 260 and 760 on the PASEC source tests. They are presented in Exhibits 11.4 and 11.5 for mathematics and reading, respectively.

The conditional means of the donated PVs on the target scales show that generally higher means are related to higher concordance scores for both mathematics and reading. Because of the volatility due to the limited number of countries, the smaller sample sizes and the dis-ordinal interaction effects among countries, a smoothing procedure was used to better represent the underlying projected conditional means and standard deviations on the target scales.

Exhibit 11.4: Boxplots of Plausible Values (PVs) from Selected Donors for Mathematics

Exhibit 11.5: Boxplots Plausible Values (PVs) from Selected Donors for Reading

For each concordance score point, the mean of the donated PVs was smoothed by applying a simple moving average (e.g., Isnanto, 2011) using a window of 7 score points. The standard deviation of PVs of each score point was smoothed in a similar way as the means of PVs, using a moving geometric mean of variances of each set of the 7 donated PV means clustered at the corresponding score level in the table. The square root of this smoothed variance becomes the smoothed conditional standard deviation.

To obtain a robust prediction for PASEC concordance scores beyond the range of 260 to 760 , where only a very small number (less than $0.5 \%$ ) of students was observed, a non-parametric regression method called Sen's slope estimator (or the Thiel-Sen estimator; Sen, 1968) was used to extrapolate for two more concordance score levels at both extreme ends. To calculate the Sen's slope estimator for the predicted mean, the median of all slopes for all pairs of ordered (ordinal) PASEC score levels and the smoothed means were used to predict the conditional means of the likely posterior distributions at the concordance score levels $220,240,780$, and 800 . Similarly, the median of all slopes for all pairs of ordered score levels and the smoothed standard deviations were used to predict the conditional standard deviations of the likely posterior distributions at the two tails of the distribution.

Exhibits 11.6 and 11.7 show the final concordance tables for PASEC mathematics and PASEC reading, respectively. The first column of each table shows the PASEC concordance score levels, either PASEC mathematics or PASEC reading. The second and third columns show the projected means and standard deviations of the conditional distribution of the latent variable on the TIMSS or PIRLS scale given the PASEC score level. The fifth and sixth columns show the lower and upper bounds of the range in which $68 \%$ of the students should fall on the TIMSS and PIRLS scale for a given PASEC score level. The fourth and seventh columns show the lower and upper bounds of the range in which $95 \%$ of the students should fall on the TIMSS and PIRLS scale for a given PASEC score level.

Exhibit 11.6: Concordance Table for PASEC Mathematics

| PASEC <br> Mathematics Score | Projected Score on TIMSS Scale |  | Lower Bound |  | Upper Bound |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Mean | SD | 95\% | 68\% | 68\% | 95\% |

| 780 | 507 | 72 | 362 | 434 | 579 | 651 |
| 800 | 521 | 72 | 377 | 449 | 593 | 665 |

As an example of the usefulness of the concordance tables, the percentages of students in each country reaching or exceeding the TIMSS ${ }^{1}$ and PIRLS ${ }^{2}$ lower benchmarks for mathematics and reading at grade 4 (indicated by a score of $\geq 400$ ) were estimated and are illustrated in Exhibit 11.8. Percentages were estimated for two sets of PVs: the PVs generated based on the Rosetta Stone assessment part (TIMSS and PIRLS linking booklets) and the projected PVs based on the concordance tables.

## Exhibit 11.8: Estimated Percentages of Students Reaching the TIMSS and PIRLS Low (400) International Benchmarks

Estimated Percentages based on Rosetta Stone

| Country | TIMSS (400) | PIRLS (400) |
| :--- | :---: | ---: |
| Burundi | $8.9(1.1)$ | $4.1(0.7)$ |
| Guinea | $16.6(2.0)$ | $19.7(2.1)$ |
| Senegal | $47.5(3.7)$ | $41.0(3.9)$ |
| Average | $\mathbf{2 4 . 3}(\mathbf{1 . 5})$ | $\mathbf{2 1 . 6}(1.5)$ |
| Estimated Percentages based on Concordance |  |  |
| Country | TIMSS (400) | PIRLS (400) |
| Burundi | $29.3(1.8)$ | $10.5(1.0)$ |
| Guinea | $10.1(1.7)$ | $15.6(2.2)$ |
| Senegal | $34.6(3.1)$ | $36.3(3.4)$ |
| Average | $\mathbf{2 4 . 7}(\mathbf{1 . 3})$ | $\mathbf{2 0 . 8}(1.4)$ |

Note: Standard errors appear in parentheses.

Overall, Exhibit 11.8 shows that while there is variability in countries' separate estimated percentages when comparing the concordance-based estimates with the Rosetta Stone part (TIMSS and PIRLS linking booklets) based estimates, the average percentages across countries provides highly comparable results. The different trend between the two parts of the table we see for Burundi (compared to the other countries) matches the patterns we see in Exhibits 5.1, 11.2 and 11.3. Without in-depth analyses of country experts, we cannot speculate regarding the source of these observed differences based on the available data. However, based on feedback from the participating countries, potential sources could be curricula differences among countries, and differences between test language and language spoken at home or in the classroom. It also should be noted that the distributions of PVs across countries are very different with Burundi showing a narrower range of imputed scores.

[^0]The variations across countries seen in Exhibit 11.8 could be related to the following limitations. First, the constructs that are measured with the Rosetta Stone assessment are not identical with the constructs measured by the PASEC assessment as indicated by the imperfect correlations between the scales. Second, the Rosetta Stone linking booklets mainly covered lower difficulty levels to adjust the assessment to participating countries. Third, the estimates are based on three countries only and somewhat smaller sample sizes per country (approximately 2,000 students), which are commonly used in national samples, compared to the full TIMSS and PIRLS assessments (approximately 4,500 students). Fourth, the scaling approach does not account for potential linking error. Therefore, the concordance should be interpreted with caution. Larger national sample sizes and adding more countries in the Rosetta Stone study would likely stabilize this estimated concordance more.

## 12. How to Use and Interpret the Concordance Tables

Concordance tables are not perfect predictions of how a student would perform on a target test (e.g., TIMSS or PIRLS). They do not provide a direct link between tests and are dependent on the characteristics of the sample. Therefore, the uncertainty of the prediction has to be taken into consideration when using and interpreting concordance tables. For example, a PASEC mathematics score of 500 does not result in a TIMSS score of 336. But, assuming we have approximately normal conditional score distributions, $68 \%$ of the generated PVs on the TIMSS scale would likely fall in the score range of 273 and 399 (if a student with similar ability took the TIMSS assessment) and $95 \%$ of generated PVs on the TIMSS scale would likely fall in the score range of 209 to 462, as shown in Exhibit 11.6. Appendix A and Appendix B provide examples of 100 randomly generated PVs based on the projected means and standard deviations of the conditional distributions in the PASEC concordance table for mathematics and reading.

Besides making inferences about the likely score range on TIMSS or PIRLS scales given a PASEC score, practitioners could also generate the likely PVs for individual students on the TIMSS and PIRLS scales by using the projected means and standard deviations from the concordance tables. To generate random PVs for the students who participated in the PASEC assessments, first, the posterior mean of the conditional distribution for each student from the PASEC population model needs to be obtained and transformed onto the PASEC reporting metric. Next, the posterior means are rounded to the nearest PASEC score levels as shown in the first column of Exhibits 11.6 and 11.7, so that the projected means and standard deviations could be assigned to individual students according to the rounded PASEC score levels. Then, the PVs are imputed based on the assigned projected mean and standard deviation of the conditional distribution for each student. There are a few ways to impute PVs based on these projected conditional means and standard deviations. In the examples shown in Appendix A and Appendix B, PVs were imputed using the "inverse of normal cumulative distribution" function in Excel. PVs for individual
students can also be imputed using a normal distribution with the corresponding conditional mean and standard deviation in SAS, R Packages, and other software tools.

Concordance tables can only provide likely projections of distributions of source test scores on a target test and, therefore, have to be understood and interpreted with caution. Differences in the measured constructs, differences in construct coverage, smaller sample sizes, linking error or curricular differences across countries result in larger conditional variance in the projections compared to equated scores on two essentially equivalent test forms that measure the same construct. Nevertheless, concordance tables provide useful and valuable information when used and interpreted correctly. Countries that participated in the Rosetta Stone linking study and administered the Rosetta Stone linking booklets can project their students' PASEC score distributions on the TIMSS and PIRLS scales. For countries which did not participate in this study and did not administer the linking booklets, the use of the concordance tables provided in this report will be an extrapolation and comes with some added uncertainty that cannot be accounted for without also conducting a Rosetta Stone data collection. Therefore, such countries are encouraged to contact IEA for possible participation in a Rosetta Stone study to obtain updated concordance tables that account for their student-specific variability in the measurement. Moreover, larger national sample sizes and adding more countries in the Rosetta Stone study will further improve the estimated concordance.

## APPENDIX C

Using the Rosetta Stone Concordance Tables - Analysis Steps

Using the Rosetta Stone concordance tables for projections of regional assessments is possible, but relies on a number of assumptions that cannot be tested unless a Rosetta Stone study is conducted for the country that utilizes the concordance. The estimation of percentages of students reaching TIMSS and PIRLS International Benchmarks described here must therefore be considered as extrapolation. The mechanics of generating such an extrapolation are:

## Analysis Steps

1. Calculate the average PV based on the PASEC sample for each student in the domain of interest, either PASEC mathematics or PASEC reading, to obtain an approximate posterior mean on the PASEC scale for each student.
2. Find the closest PASEC level in the concordance table for each student (source test); the corresponding projected mean and standard deviation (SD) on the TIMSS or PIRLS scale for the closest PASEC level should be assigned to each student.

Example: For a student with an average PV of 505 based on 5 PASEC mathematics PVs, the closest PASEC mathematics level is 500; the assigned projected mean and SD on the TIMSS scale are 336 and 63, respectively (see the concordance table for PASEC mathematics in Exhibit 11.6). For a student with an average PV of 505 based on 5 PASEC reading PVs, the closest PASEC reading level is 500; the assigned projected mean and SD on the PIRLS scale are 297 and 71, respectively (see the concordance table for PASEC reading in Exhibit 11.7).
3. Impute 5 new projected TIMSS mathematics or PIRLS reading PVs (target test) based on the assigned projected mean and SD (for mathematics or reading) of the conditional distribution for each student. PVs for individual students can be imputed using a normal distribution with the corresponding projected mean and SD in SAS, R Packages, EXCEL, and other software tools (this step is repeated five times to get 5 PVs ).
4. These 5 sets of projected PVs can then be used to estimate the percentages of PASEC students reaching the TIMSS or PIRLS international benchmarks, Advanced (625), High (550), Intermediate (475), Low (400). The final percentage of reaching a benchmark, $t_{0}$, is the average of the 5 percentages, $t_{m}$, calculated based on 5 set of projected PVs:

$$
\begin{equation*}
t_{0}=\frac{1}{5} \sum_{m=1}^{5} t_{m} \tag{C.1}
\end{equation*}
$$

5. The standard error needs to be calculated using proper weights and formulas to include imputation variance and sampling variance. The imputation variance is simply the variance of the 5 percentages of reaching the benchmark (from step 4) then multiplied by a factor $\frac{6}{5}$ :

$$
\begin{equation*}
\operatorname{Var}_{i m p}\left(t_{0}\right)=\frac{6}{5} \sum_{m=1}^{5} \frac{\left(t_{m}-t_{0}\right)^{2}}{4} \tag{C.2}
\end{equation*}
$$

For each set of PVs, the sampling variance is the variance among the different percentages calculated by using each set of replicate sampling weights (which are usually included in the data file); $n$ is the number of replicate weights:

$$
\begin{equation*}
\operatorname{Var}_{s m p}\left(t_{m}\right)=\sum_{h=1}^{n}\left(t_{m h}-t_{m}\right)^{2} \tag{C.3}
\end{equation*}
$$

The final sampling variance is the average of the sampling variance from the 5 set of projected PVs:

$$
\begin{equation*}
\operatorname{Var}_{s m p}\left(t_{0}\right)=\frac{1}{5} \sum_{m=1}^{5} \operatorname{Var}_{s m p}\left(t_{m}\right) \tag{C.4}
\end{equation*}
$$

The square root of the sum of imputation variance and sampling variance is the standard error of the percentages of reaching international benchmarks:

$$
\begin{equation*}
S E=\sqrt{\operatorname{Var}_{i m p}\left(t_{0}\right)+\operatorname{Var}_{\text {smp }}\left(t_{0}\right)} \tag{C.5}
\end{equation*}
$$

6. Do all the steps for each domain of interest (mathematics or reading) separately using the (mathematics or reading) concordance table
7. The estimated percentages and standard errors can be reported noting that the projection for each new country relies on the concordance based on samples from only 3 other countries, not including the present country. Therefore, there are sources of error variance and bias that are not reflected in the projections.
